New soft robots really suck: Vacuum-powered systems empower diverse capabilities

Matthew A. Robertson and Jamie Paik*

We introduce a vacuum-powered soft pneumatic actuator (V-SPA) that leverages a single, shared vacuum power supply and enables complex soft robotic systems with multiple degrees of freedom (DoFs) and diverse functions. In addition to actuation, other utilities achievable by vacuum pressure include gripping and stiffening through granular media jamming, as well as direct suction adhesion to smooth surfaces, for manipulation or vertical fixation. We investigate the performance of the new actuator through direct characterization of a 3-DoF, plug-and-play V-SPA Module built from multiple V-SPAs and demonstrate the integration of different vacuum-enabled capabilities with a continuum-style robot platform outfitted with modular peripheral mechanisms. We show that these different vacuum-powered modules can be combined to achieve a variety of tasks—including multimodal locomotion, object manipulation, and stiffness tuning—to illustrate the utility and viability of vacuum as a singular alternative power source for soft pneumatic robots and not just a peripheral feature in itself. Our results highlight the effectiveness of V-SPAs in providing core soft robot capabilities and facilitating the consolidation of previously disparate subsystems for actuation and various specialized tasks, conducive to improving the compact design efficiency of larger, more complex multifunctional soft robotic systems.

INTRODUCTION

Robots that operate in highly variable environments or in close cooperation with humans require both robustness and adaptability to ensure reliability and safety. These features can be accommodated most easily by adding compliance to a robotic system, which can be achieved either actively through impedance control methods (1, 2) or passively through compliant mechanical components and materials. In part, the advantage of a materials-based approach to creating compliant systems is to offload some of the burden of complexity in control to morphological and material computation, in a sense, to achieve robust and adaptable behavior (3, 4). This latter strategy has been the recent focal point of the field of soft robotics, where inherently compliant and flexible materials such as silicone rubber are used to fabricate primary structural and active robot components (5). Various forms of soft pneumatic actuators (SPAs) powered by pneumatic pressure have been developed in this domain to complement the nature of these soft materials, which stretch and bend through inflation or deformation of elastic chambers to produce useful mechanical work (6–16).

This relatively new approach to robotics has yielded mobile platforms, manipulators, and other soft structures that are applicable in increasingly complex applications. Rough terrain locomotion, delicate handling, and human interaction tasks all benefit from the natural quality of SPA-driven systems to conform or yield safely to rigid environmental constraints without sacrificing the functional purpose of the device (17–19). Although now traditional soft pneumatic systems afford these benefits already using positive pressure, recent interest in negative pressure systems aims to improve these qualities further. Exploiting the effect of mechanical buckling to generate controlled force, vacuum-driven soft, muscle-like actuators have been successfully demonstrated using standard soft robotic materials and fabrication techniques (20, 21). This type of actuator offers implicitly fail-safe operation, being limited by environmental pressure from actuating beyond a maximum force and displacement, and directly enables contractile motion, more similar to biological muscle than the expansion-based motions of many positive pressure-driven soft actuators.

Following previous efforts (20, 21), we introduce a vacuum-powered SPA, the V-SPA, to expand the diversity and utility of this versatile power source for new soft robots. In comparison with the few existing examples of vacuum-driven actuators, this new type of actuator is exceptionally rapid to fabricate for proficient iteration through multiple designs. This is a result of requiring no molds or sacrificial compounds and being constructed primarily of readily available, manufactured foam sheets. The use of porous foam structures in soft robotics has recently been investigated to a limited extent for various novel benefits. With self-manufactured poroelastic foam, a bioinspired fluid pump was developed to showcase the utility and simplicity of foam-based compliant actuation (22). Following a similar method to fabricate poroelastic foam from a moldable compound infused with a fugitive salt porogen, highly customized inflatable structures can be sculpted in free form for laboratory, art, or classroom educational purposes (23). Other work has explored the use of bicontinuous metal-elastomeric foam to achieve variable stiffness and self-healing properties (24). Although most of these methods have been applied toward the fabrication of SPA devices powered by positive pressurized air, the application of vacuum to foam structures is an approach that combines the advantages of vacuum power with some of those inherited from the properties of the foam material itself, including impact resistance, robustness, and storage-friendly "crushability" (25). Our soft actuator exploits this combination, enabling a wide range of soft robotic applications, including safe, lightweight, wearable devices, collaborative machines, or packable mobile robots that are space- and energy-efficient, suitable for remote deployment or even possibly flight (see Fig. 1).

Capitalizing on the vacuum supply available for actuation, vacuum-based soft robotic systems can also leverage this source to incorporate other functions and features powered by negative pressure, without the need for an additional power supply or additional subsystem infrastructure. Vacuum-powered mechanisms have been shown to
enable operations useful to soft robots, including gripping (26), suction (27), and stiffness tuning (28–31). By adding a lightweight alternative for actuation to this variety of available vacuum-driven mechanisms, V-SPAs open the opportunity to expand the capability of soft robots while actually minimizing the size and complexity of their design and implementation. The seamless integration of these mechanisms through a common vacuum supply not only yields more efficient soft robot design but also subsequently facilitates high-order soft pneumatic systems with many degrees of freedom (DoFs), which are still relatively scarce in the field of soft robotics. To demonstrate this facility, we use V-SPAs in a typically complex and difficult multi-DoF robot morphology, generally referred to as a continuum robot. Also known as hyper-redundant robot manipulators, trunks, tentacles, or snakes, these narrow structures often consist of a linear chain of repeating modular units, each with single or multiple active DoFs. This concept enables a high degree of kinematic maneuverability and flexibility for either manipulation (32–36), positioning (31, 37), or locomotion (38–40) tasks to account for variable environments or system objectives. Although the low mass of the V-SPAs themselves makes such an architecture with many DoFs more feasible, dealing with the practical difficulty imposed by cumbersome, overlapping pneumatic supply lines routed from a central control source to many independent actuator units often limits its realistic execution. To overcome this barrier and allow the consolidation of multiple vacuum-based mechanisms into the same platform through a common vacuum supply line, we used a decentralized, modular design approach.

This work validates the integration of our actuator in multifunctional vacuum-driven soft robotic systems by experimental demonstration of interaction task versatility and mechanical performance tuning of physical properties through the use of plug-and-play control and design methods. By introducing actuation technology and demonstrating the combination of different functions made possible through a negative pressure pneumatic power supply, we help to establish vacuum power as a substantial alternative class of soft robotics that offers unique and important potential for realizing complex and advanced systems.

**RESULTS**

**Vacuum-powered soft pneumatic actuator**

We designed and developed a critical robotic component, the V-SPA, which is characterized by its implicit reliability and safety through the utilization of vacuum power and the robust properties of a foam core. This new actuator is simple in design and easy to fabricate without the need for either an internal or an external mold. It is composed of a laser-cut, off-the-shelf foam core and thin, brushed-on layers of silicone rubber and can be manufactured from scratch—ready to be used in less than 2 hours. The foam core acts as an internal scaffold over which uncured silicone rubber can be applied to form a thin, sealing layer around the open-celled foam, as can be seen in fig. S1. This creates an enclosed, airtight structure that is only sparsely filled with soft, porous material. Whereas conventional SPAs or other vacuum actuator designs feature completely hollow inner cavities, the use of foam allows the wall thickness of V-SPAs to be much thinner because it provides much of the structural support typically given by a thicker wall needed to maintain a nominal actuator shape. This difference in material wall thickness helps to offset the added mass of the core, yielding an ultimately lighter weight actuator overall. Upon activation, vacuum is applied to the internal volume through a supply channel, and the entire V-SPA structure collapses inward to produce tensile force that can be used for actuation. The low-density core is easily deformed and crushed when vacuum is applied but immediately provides elastic return in conjunction with the elasticity of the outer silicone membrane after actuation to return the actuator to its original shape. The activation of a circular V-SPA array can be seen in movie S1.

In soft robotics, foam-based vacuum-powered actuators offer a solution to improve the efficiency of soft systems, by reducing mass in actuators, allowing for the integration of additional mass components...
onboard to enable fully self-contained systems, including batteries and pressure (or direct vacuum)–generating pumps. This reduction in the total system mass budget also makes room for larger systems with more DoFs, enabling further complex behavior. Although vacuum power is not suited for every application, in part due to limited force production at atmospheric pressure, for use at small scales where this force limit is perhaps beyond maximum requirements, and where this limit offers a unique safety feature because it prevents actuating beyond the force imposed by external pressure, V-SPAs hold a unique advantage at substantially low cost in weight, materials, and production effort.

**Scalable, reconfigurable soft robot**

We developed a robotic platform using V-SPAs to power hybrid (41) modular units, known as V-SPA Modules, which contain both soft actuators and rigid components necessary for their power and control. This architecture was chosen to practically implement V-SPAs in an example soft robotic system with enhanced and diverse capabilities. The modular design of the units enables rapid, simplified restructuring and control of various robot configurations for easy testing and validation of vacuum system extensibility. Specifically, these modules allow the addition or subtraction of mechanical DoFs with little or no physical design effort through standardized pneumatic and electrical network connection ports. Other peripheral device modules with different functionalities can also be easily combined with the actuators in the same way. To eliminate the effort of develop-

![Image of V-SPA Module step response characterization](image-url)
Modules presented in Fig. 2 was performed by measuring the angular step response of a module under varied conditions. From the different response profiles, metrics were obtained relating actuator and module performance to different loading and supply pressure conditions. The measured characteristics are summarized in Table 1.

Each V-SPA Module connects in series to another through connections on the top and bottom to a central pneumatic supply line, power and ground lines, and communication bus, shown in Fig. 3A. The overall structure of the resulting network of modules can be seen in Fig. 3B with the note that this architecture is not only limited to efficiently integrating actuators alone but also designed to facilitate rapid and simple extension of many different module types for vacuum (or other) pneumatic robotic systems. Commands to individual actuators in each networked module are relayed over a communication signal line using a robust serial protocol designed initially for low-cost red-green-blue (RGB) light-emitting diode (LED) serial displays. Because each channel of every module in the network is identified sequentially and not through a unique address, this allows modules to be added or subtracted in a generic way that does not affect the low-level control programming. Although such modules could be used in various combinations, in a multitude of different robot topologies, the nominal configuration studied here in direct linear arrangement allowed for the demonstration of many interesting features enabled by V-SPAs and vacuum power alike.

**Hyper-redundant soft robot performance**

We first tested the operation of a five-module robot to quantify its performance in the simplest form, as a soft manipulator arm. The workspace and repeatability of the robot’s three principle directions of motion from an initially vertical standing orientation were measured using an external OptiTrack motion capture system to demonstrate the practical utility of a V-SPA–based system. The proximal end of the robot was fixed to a stationary base, and three markers were attached to the distal end to track the three-dimensional (3D) trajectory of their centroid, treated as the robot end point. For this preliminary evaluation, every module in the robot was synchronized to move the end point virtual marker through three distinct locations (roughly 0°, 120°, and 240°) representing the robot’s principle directions of motion, as shown in Fig. 4A. Binary activation signals (on/off) were used to achieve the maximum bend in each of these directions, although independent control of each of the 15 total V-SPAs in the robot (three per module) is possible, and continuous motion of each actuator or combination of actuators in a single module could also be achieved using PWM signals to produce motion in any arbitrary angular direction.

The robot end point position was measured for 10 cycles through each location, and a 2D error ellipse (95% confidence interval) was calculated for each set of 10 points in each of the three locations (see movie S3 for a video of the 10-cycle trial test). The length of the ellipse major axes, corresponding to the largest variability in end point positioning, was averaged for all three locations. For a five-module robot, the average error recorded across the three principal locations tested was found to be ±3.4 mm. This corresponds to an average repeatability measure of ±0.68-mm accuracy per module. Individually, the range of accuracy across each of the three respective directions differed slightly as a result of variable construction and individual actuator performance, with the lowest variability in a particular direction (actuator 3) measured to be ±1.9 mm for the robot as a whole or ±0.38 mm per module along that axis. Although the path and final position of the robot end point in each direction are seen to be repeat-
diversity of applications for soft robots, including enhanced mobility and controllability enabled by the configurations depicted in Fig. 4C, highlighting the efficacy and versatility of V-SPAs and vacuum-based soft robotic systems as a whole.

**Interaction task: Suction manipulation**

As a first test of the versatility of the vacuum power supply, a suction manipulator component was added to the end of the positioning arm, maintaining a modular design approach. A snap-fit 3D printed part was attached to the distal robot module to provide the structural basis of the suction module, including a modified off-the-shelf soft suction cup. The new peripheral module was connected to the shared vacuum power supply, and a custom networked control valve was plugged in series to the output electrical interface of the distal actuator module to be controlled along the common control signal bus. A silicon tube connected the valve output to the internal volume of a soft suction cup through a hole at the top, enabling it to be actively depressurized or vented to the atmosphere for controllable attachment or detachment to objects. The soft continuum manipulator arm was then tested in a simple reaching and manipulation task of smooth acrylic containers to demonstrate the performance of combined actuation and suction manipulation. The multifunctional system was able to successfully "grasp" and relocate objects from a starting location to target bins, as shown in movie S4.

**Interaction task: Vertical window climbing**

Integrating lightweight actuation with other vacuum-based mechanisms enables capabilities beyond positioning and manipulation tasks. We demonstrate further the advantages to combining these mechanisms by reconfiguring V-SPAs and suction cup modules into a soft robot capable of vertical climbing on smooth surfaces. The actuator and architecture previously presented readily accommodated two vital requirements for this type of robot: to provide active motion for climbing and selective attachment and release of robot footholds while maintaining low enough weight to not hinder the effect of those capabilities. The low-mass foam core V-SPAs are naturally well suited to this application, and the modular, shared vacuum supply architecture of the complete soft robotic system enables the efficient integration of the active functions necessary for vertical climbing in a nearly self-contained soft robotic system that can scale surfaces such as glass windows. With only an open-loop, fixed-gait pattern controller and without optimizing timing parameters to find the maximum speed, demonstrated gait was measured to be 2 mm/s or 0.01 body lengths per second (BL/s). Although the climbing robot we present here lacks an onboard electrical power supply and pneumatic vacuum generation source, we verified that it is capable of carrying an additional payload up to 70 g, which may be useful for accommodating the remaining components to enable a more autonomous robot in the future. Figure 5A shows the progression of the climbing robot, and movie S5 shows testing with increasing external payload, with an evident corresponding reduction in climbing speed. Although this change in climbing performance can be attributed...
in part to variable actuator functionality in response to load, this can also be a factor of the robot design, which included a passive DoF at the lower foot needed for climbing and an offset of the payload mass resulting in a moment that pulled the robot away from the wall and reduced step size.

**Interaction task: Multimodal locomotion**

Alternate modes of locomotion were also found to be possible using the modular vacuum-driven soft continuum robot system suitable for potential use in diverse and variable environments. Up to five V-SPA Modules were assembled in series and programmed to achieve two distinct gaits following strategies investigated previously for continuum style snake robots: a wave gait and a rolling gait. The first of these is shown with a sequence of video frames in Fig. 5B depicting the progression of the forward wave gait over a flat, level surface with a measured average speed of 5 mm/s (0.05 BL/s). As a secondary but inherited feature of the modular robot structure, the reconfigurability and robustness of the continuum robot are also exhibited in Fig. 5C, where locomotion is preserved and even improved in terms of average speed, measuring 11 mm/s (0.08 BL/s) after two modules were removed from the robot, without requiring any changes to the gait controller. The increase in speed results only from an inherent change in vacuum supply air flow, which is restricted more for every module attached. Better designs could compensate for this by providing a central supply line with larger diameter.

Lateral motion was also accomplished using a rolling gait, expanding the utility of the mobile robot to suit different locomotion objectives. This gait, shown in Fig. 5D, is capable of much higher locomotion speeds (an average speed of 60 mm/s or 1.33 BL/s) than the wave gait of any robot length; however, this is possible only at the cost of a larger operational workspace (wider body span relative to the direction of travel). In practice, the multimodal functionality of this type of robot may be exploited to achieve fast motion over generally wide, open terrain using the rolling gait, whereas slower, cautious navigation through narrow passages, gaps, or obstructions could be approached using the wave gait, which operates within a more slender body width. A demonstration of the continuum robot gaits described can be found in movie S6.

**Mechanical tuning: Jamming-based stiffening**

Although our initial workspace testing indicated that the compliance of the arm does not significantly affect repeatability, manipulation testing of the soft arm, as well as experience from literature, reveals that the controllability of such a soft structure to precise locations
remains a challenge. This was apparent from qualitative observations of object manipulation/relocation tasks, where the object mass in addition to the inertia of the arm itself led to oscillatory behavior. Although closing the active control loop to better maintain positioning and path following is likely needed for the best results, these tasks would benefit from other methods of “passive control,” including the ability to tune mechanical system parameters of soft robotic devices themselves. In particular, this motivated the design and integration of a peripheral variable stiffness module to provide the ability to change the overall rigidity or passivity of the soft arm.

Distributed across the length of the continuum robot arm, this module is composed of multiple stiffening pillars in parallel with each actuator module and uses jamming of enclosed granular media (ground coffee) driven by actively controlled vacuum to vary the stiffness of the overall structure. Figure 6 shows the resulting stiffness characteristics of the soft continuum robot fitted with the stiffening module when force is applied through a high-strength nylon thread (fishing line) at the distal module perpendicular to the axis of the vertically mounted robot. Jamming pillars were spaced in three columns around each V-SPA Module and powered together with 88.5% vacuum when activated. The tested directions are grouped as either a pull in the direction of a jamming column, toward the vertex of the triangle formed from a top view of the three columns, or toward an edge, between two jamming columns. Five cycles were performed in each direction, with the result for each condition provided as an average of these trials. The measurements indicate an increase in stiffness in every direction when jamming is enabled, with the greatest increase always in the direction of a vertex, and hence the most direct compression of a single jamming column, with increases of 38.8, 48.5, and 31.7% when vacuum is applied versus when it is not. In the direction of an edge, the stiffness was only moderately increased from their activation, by 15.1, 31.5, and 17.3% for the three edge direction loading conditions. A diagram of the test setup is shown in fig. S2, along with a depiction of the fabrication process used to produce the granular jamming units.

The jamming modules in this demonstration are coupled and joined to the same controlled vacuum input but could equally be included as part of more advanced actuator modules with internally integrated, independently controlled jamming pillars for more selective mechanical tuning capability of a soft structure. In addition, only granular jamming was explored for this investigation of mechanical tuning, but stiffening with vacuum can also be achieved using flexible sheet materials sandwiched between air-sealed plastic film to achieve similar or possibly improved results (30, 49).

**DISCUSSION**

The actuators presented here and the combined example applications illustrate the versatility of vacuum-based SPAs constructed from simple materials and methods. The fabrication procedure for V-SPAs reduces the time, tools, and cost required for creating actuators for soft robots by using only 2D manufacturing methods and eliminating conventional molds, which allows rapid, batch production from minimal effort in comparison with other SPA types. Although conventional molding techniques inherently produce more uniform actuator structure and reduced variability between different actuators, the accuracy and repeatability of individual V-SPAs are not significantly affected as shown here, despite the variable wall thickness produced from manual application of silicone rubber layers. This improvement in actuator fabrication serves to decrease the design and development cycle time, leaving more room for focus on the system-level development of complete and useful soft robots. Toward the same goal, the use of vacuum as a primary pneumatic supply source to power V-SPAs enables more efficient integration of other vacuum-based mechanisms in a single soft robotic system, allowing for more complex and diverse soft robot capability. This potential was effectively demonstrated through the use of modular units, which allow many vacuum-driven mechanisms, as well as many redundant actuators, to be seamlessly combined and tested in different soft robot configurations. Furthermore, unlike most other SPAs (6–16), using a single source of pneumatic power significantly reduces the overhead cost of redundant subsystem infrastructure needed in comparison with the alternative case, where components—such as regulators, distribution manifolds, and central supply lines—cannot be shared. This simplification saves weight and design effort. V-SPAs likewise support the implementation of systems with many active DoFs, through the use of lightweight foam material as a central component,

V-SPA Assembly

Although the advantages of foam V-SPAs are promising for the
development of a new type of complex soft robots, they are not with-
out certain fundamental and practical limits. The capacity of vacuum
to produce useful contractile work in an actuator is limited by the
pressure of its external environment. For nominal use at standard
atmospheric pressure, this serves as an absolute limitation; however,
in more creative applications such as use in alternative environments
(underwater or exoplanetary), this “limit” can be treated as a param-
eter to be considered in design. In any
case, for a given setting, this coupling to
the environment imposes a boundary on
the performance of the actuators and
hence the system as a whole. Beyond this
inherent physical limit, the specific de-
design implementation of V-SPAs in soft
robotic systems can also be seen as a lim-
itation, because the actuators do not pro-
vide a consistent mechanical constraint
alone to direct their motion unless used
carefully. Although the 2D manufactur-
ing method used here can be adapted to
allow for more complex shapes condu-
cive to directed buckling (bellows-like
shapes) and actuation, the most effective
method for this is through the support of
external constraints, such as reliance on
the stiffness of an attached surface to re-
strict the buckling of the actuator along
that interface, allowing it to occur only
between two moving bodies as desired. In
addition, external structures can help
impose constraints and define actuator
motion, such as the stiffness of other
coupled actuators or as a well-defined
joint axis of rotation (see movie S1). The
rigid upper and lower plates, as well as
the flexible but nonstretchable central
conduit of the V-SPA Modules produced
here, serve these purposes in part, ensur-
ing that the contraction of the actuators
results primarily in rotational motion.

The simplicity of this V-SPA concept
encourages the development of even more
creative techniques and applications for
soft actuation. Other methods of elastic foam production could be used in the
future to create complex 3D structures, possibly deviating from the strict use of
off-the-shelf materials. Variable stiffness
skin components of either different thick-
nesses or material could be used to gen-
erate more complex actuation patterns
for increasingly advanced V-SPA designs
using multimaterial 3D printers or other
standard soft robot fabrication tools. Re-
gardless of the implementation method
or application, future soft robots will
benefit from exploring and exploiting the
benefits of both foam-based materials

and vacuum power as new viable means to achieving versatile capabilities for environmental interaction and controlled modulation of mechanical system performance.

MATERIALS AND METHODS

Objectives

The objective of this study was to characterize and validate the performance and integration of V-SPAs in multifunctional vacuum-based soft robots. We explain the design procedure and fabrication techniques for the actuators and multi-DoF actuator modules, and describe test methods for obtaining performance metrics for each.

Actuator design and fabrication

The fabrication process of a V-SPA shown in Fig. 7 begins with a basic preform structure, to act as a mount during application of the outer rubber layer and as a mask over the foam where connection of a vacuum supply to the internal actuator cavity is eventually made. For the actuators produced here, the preform also served to create a smooth flat surface on the same side as the supply access mask when peeled off, so the actuator will form a good seal when glued to an equally smooth flat supply distribution plate.

The actuator itself is composed of 2D foam core shapes manufactured from a sheet of open-celled polyurethane foam (12.7-mm-thick polyurethane foam, McMaster-Carr, 8643K511) and rigid paper dividers. The porous foam cores serve as the main actuator body, whereas the paper dividers help reduce the buckling on the upper surface of the actuator and, at intervals along the height, enforce deformation primarily in the vertical direction. A CO₂ laser was used to cut many foam core and paper divider components from a single sheet at once, allowing batch production of the actuators. The foam cores and paper dividers are assembled in a stack with cyanoacrylate gel glue and then glued to the preform. After preparation by mixing and degassing, two coats of ELASTOSIL M 4601 silicone rubber (Wacker Chemie AG) are spread with brush-like strokes onto all exposed surfaces of the foam core using a flexible spreader (thick cardboard) while being cured at 50°C between coats. Once cured, the actuators can be removed from the preform and attached to a vacuum supply or used directly on the preform by applying vacuum to the vent hole through the base.

Although the basic construction of V-SPAs is described above, many variable parameters affect actuator performance. One of the leading design variables is geometry, because it pertains to dimensions that are easy to change, like actuator shape, and to others that are more difficult to manipulate, like the porosity of the foam used. As a starting point, we investigated only minor changes in actuator morphology toward a very specific goal—to create a circular module with three actuators and room at the center to pass wiring and a central pneumatic supply. This bounded the overall shape of the actuator to be used, but small improvements were added in an effort to achieve specific behaviors and subjectively improved performance criteria, in this case maximal linear deflection. To increase the directionality of the actuators, we selected a particular geometry for the foam core that would allow inward compression and buckling of sidewalls without interference limiting the downward actuator stroke. This helped to direct actuator contraction to the axial direction, perpendicular to the top plane of the original foam sheet. Then, multiple foam chambers were created by stacking individual foam cores to increase the actuator range of motion. To create independent porous volumes within a single actuator, we assembled thin 0.2-mm heavy-gauge paper dividers between two foam cores glued together in a stack to form an internal membrane. The dividers contain a 6-mm hole at the center to allow air flow between chambers while still enforcing separation. Without this membrane, the overall structure of the two-core actuators would yield an effectively taller actuator, which, for the same given cross-sectional area, would yield a more horizontal than vertical mode of collapse upon vacuum activation. Although a parametric study was not conducted to properly determine an ideal V-SPA compression ratio, it is plausible that an optimal relationship exists to best select actuator height based on cross-sectional geometry (aspect ratio) for linear actuation. For planar actuator methods, this ratio is the most accessible parameter to optimize; however, an ideal actuator shape would incorporate geometric contours along the “walls” of the foam core to increase stress concentrations for uniform buckling, much in the same way a corrugated bellows collapses. This partly achieved by creating multichamber actuators, whose stiff dividers act similarly to limit the stress along designated rings around the actuator perimeter. A separate study could investigate the optimal size and number of separate foam core chambers needed to maximize deflection or force using this design method.

Other factors—including foam type and composition, porosity, and elastomer coating material—are expected to greatly affect the performance of V-SPAs, but the methods for testing these variations involve greater effort. To begin, different foam materials and elastomers behave differently, and not all combinations allow for full curing of multi-part elastomers that chemically interact. Open-cell foam materials of different composition and porosity are also limited as off-the-shelf components but can be produced from scratch for testing if desired. These factors limit the possibility for ready empirical parameterization testing. Perhaps a more controlled and available approach would be to simulate the effect and performance of actuator deformation using finite element modeling techniques, but this proves to be difficult and holds no greater advantage: Accurate models of this type still require empirical testing to determine material property values. Nevertheless, as data and models improve over time, this technique will prove to be invaluable as actuators, such as the V-SPA, are adopted for further use.

The use of primarily off-the-shelf materials allows this new type of actuator to be easily produced with low resources, partly to extend the accessibility and scope of soft robot construction and research, especially toward the realm of lower education STEM (science, technology, engineering, and mathematics) outreach programs. However, the concept of foam vacuum actuation is not exclusively tied to these materials and methods of manufacture. We capitalized greatly from laser-cutting machines for fabricating 2D foam core shapes, but this tool is not required and virtually any method for cutting foam sheets will suffice. Early prototypes of V-SPAs were built from scissor-cut foam cores attached to the end of wooden dowels (to serve as a mount and mask) and could be directly super-glued to a supply tube with the outer rubber skin used to seal the foam and fix the tube to the actuator in a single step. As an alternative to brushing on the outer rubber layer, dipping might also be used to coat an entire foam core for even faster manufacture time.

V-SPA Module control and characterization

Control of each V-SPA Module connected in series is achieved over a single-wire interface, enabled by a low-cost and readily available integrated circuit (IC) originally designed for controlling individual
LED pixels in networked displays (Worldsemi, WS2811). The IC is repurposed to supply an activation signal to onboard amplifiers for direct control over three embedded solenoid valves (Lee, LHDA0531115H) shadowing the operation of each color channel of an RGB LED. A significant benefit of this IC is that it tolerates real-time reconfiguration of hardware, enabling plug-and-play functionality of the V-SPA Modules. Robots can therefore be reduced or extended fundamentally to any number of modules on a single bus over relatively large spans, with only practical limitations imposed by random-access memory (RAM) and electrical power required. With standard microcontrollers, such as Arduino, hundreds of IC-enabled modular units can be controlled in a serial network through a single wire with little additional local electronics hardware, compared with alternative networking schemes (I2C, CAN, and direct serial), which require more local computational power. Figure 4B depicts the topology of this network architecture, whereas a schematic of the internal electronic connections to the LED driver IC can be seen in fig. S3.

To determine the performance characteristics of a V-SPA Module, we empirically measured a step response for multiple values across different conditions. Each response was averaged from three different actuators, cycled 10 times each. This process was repeated for 10 conditions of varying load and 10 conditions of varying input vacuum. Load was applied by calibrated weights through a cable hung over a pulley and attached to a short lever arm fixed to the module. Vacuum pressure was varied by changing the positive supply pressure to a vacuum ejection module (SMC ZH05B). The cycles for all three actuators in each condition were averaged to obtain a single representative step response curve from which performance metrics were extracted. The maximum angular motion is directly measured, whereas the rise time is found from the time between response crossings at 10 and 90% of the maximum angular deflection. The initial angular velocity is also found in this region, from a linear fit to the first half of the actuator motion (up to 50%), where the response curve is dominantly linear.

Blocked moment measurements of the V-SPA Module were obtained using a six-axis force and torque sensor (Nano17 SI-25-0.25, ATI Industrial Automation) mounted to the upper plate of the module constrained at the base in a rigid test fixture. The reported value was averaged from individual activation of three different actuators, cycled 10 times each. With an alternate setup, the average mechanical power output of a V-SPA Module was also estimated through measurements of displacement, $\Delta h$, and time, $\Delta t$, for a known mass, $m$, fixed to a cable hung over a pulley (assumed to be a constant force, $F = mg$), and driven by a short arm attached to the module, following $P = F \cdot \Delta h / \Delta t$. The metrics of torque and power were normalized by the mass of the module and the actuator alone to compute specific torque ($\tau_s$), specific power ($P_s$), and specific energy ($E_s$). Although the latter of these is relatively low compared with other vacuum-powered actuators (20), with $P_s = 5 \text{ W kg}^{-1}$ and $E_s = 1.2 \text{ J kg}^{-1}$, the value of specific torque is found to be relatively high, with $\tau_s = 45.3 \text{ N m kg}^{-1}$ (45.3 N mm g$^{-1}$), more than five times that of the modular dc motor–powered actuators designed for a conventional rigid continuum robot, the Unifit Snake (50).
